Learning-Based Spectrum Sensing and Access in Cognitive Radios via Approximate POMDPs

Bharath Keshavamurthy[®], Graduate Student Member, IEEE, and Nicolò Michelusi[®], Senior Member, IEEE

Abstract—A novel LEarning-based Spectrum Sensing and ² Access (LESSA) framework is proposed, wherein a cognitive 3 radio (CR) learns a time-frequency correlation model under-4 lying spectrum occupancy of licensed users (LUs) in a radio 5 ecosystem; concurrently, it devises an approximately optimal 6 spectrum sensing and access policy under sensing constraints. 7 A Baum-Welch algorithm is proposed to learn a parametric 8 Markov transition model of LUs' spectrum occupancy based on 9 noisy spectrum measurements. Spectrum sensing and access are 10 cast as a Partially-Observable Markov Decision Process, approx-11 imately optimized via randomized point-based value iteration. 12 Fragmentation, Hamming-distance state filters and Monte-Carlo 13 methods are proposed to alleviate the inherent computational 14 complexity, and a weighted reward metric to regulate the 15 trade-off between CR's throughput and interference to the 16 LUs. Numerical evaluations demonstrate that LESSA performs 17 within 5% of a genie-aided upper bound with foreknowledge 18 of LUs' spectrum occupancy, and outperforms state-of-the-19 art algorithms across the entire trade-off region: 71% over 20 correlation-based clustering, 26% over Neyman-Pearson-based 21 spectrum sensing, 6% over the Viterbi algorithm, and 9% over 22 adaptive Deep Q-Network. LESSA is then extended to a dis-23 tributed Multi-Agent setting (MA-LESSA), by proposing novel 24 neighbor discovery and channel access rank allocation. MA-25 LESSA improves CRs' throughputs by 43% over cooperative 26 TD-SARSA, 84% over cooperative greedy distributed learning, 27 and 3× over non-cooperative learning via g-statistics and ACKs. 28 Finally, MA-LESSA is implemented on the DARPA SC2 plat-29 form, manifesting superior performance over competitors in a 30 real-world TDWR-UNII WLAN emulation; its implementation 31 feasibility is further validated on an ad-hoc distributed wireless 32 testbed of ESP32 radios, exhibiting 96% success probability.

33 Index Terms—Hidden Markov Model, cognitive radio, spec-34 trum sensing, POMDP.

I. INTRODUCTION

OGNITIVE radios (CRs) have been touted as instrumental in solving resource-allocation problems in resource-seconstrained radio environments. Their adaptive computational intelligence facilitates the dynamic allocation of scarce network resources, particularly the spectrum. With the advent of fifth-generation cellular technologies [15], a multitudinous

array of devices will be brought into the wireless commu- 42 nication ecosystem, resulting in an enormous strain on the 43 available spectrum resources. Dynamic spectrum access, the key defining feature of CR networks, is being widely studied 45 as a solution to the problem of spectrum scarcity, in both military and consumer spheres: CRs intelligently access portions 47 of the spectrum unused by the sparse and infrequent transmissions of incumbents or licensed users (LUs), in order to deliver their own network flows, while adhering to interference compliance requirements. In order to intelligently access the spectrum white-spaces, CRs need to solve for a spectrum sensing and subsequent access policy based on noisy observations of the occupancy behavior of LUs. Yet, critical design limitations, driven by energy efficiency requirements or constraints on sensing times [14], prevent CRs from sensing simultaneously the entire spectrum of interest. Under these constraints, CRs can only sense a small portion of the spectrum to determine access opportunities, as studied in [6]-[10], [12]-[14]. However, this approach is quite conservative, since it does not allow CRs to access the large pool of subcarriers that have not

LUs' occupancy may exhibit correlation across both time and frequency, as demonstrated in [16] and visualized in Fig. 2(a). Exploiting this time-frequency correlation structure may significantly improve white-space detection, by enabling CRs to predict the occupancy state of those subcarriers that have not been directly sensed, and may unlock additional spectrum access opportunities. In this paper, focusing first on deployments with a single CR, we propose LESSA, a LEarning-based Spectrum Sensing and Access framework that leverages these time-frequency correlations: a CR learns a parametric time-frequency correlation model underlying the occupancy behavior of LUs in the radio ecosystem; concurrently, it exploits this learned model to construct an approximately optimal sensing and access policy using a Partially Observable Markov Decision Process (POMDP) formulation, 77 solved via randomized Point-Based Value Iteration (PBVI). We propose fragmentation techniques, Hamming distance state filters and Monte-Carlo methods to alleviate the inherent computational complexity, and we introduce a weighted reward metric to regulate the trade-off between CR's throughput and interference to the LUs, unlike the state-of-the-art. Our numerical evaluations demonstrate that LESSA improves spectrum occupancy across the entire trade-off region, over state-ofthe-art algorithms including correlation-based clustering [3], Neyman-Pearson-based spectrum sensing [13], the Viterbi algorithm [9], and adaptive Deep Q-Network (DQN) [2]. 88

Furthermore, we extend LESSA to Multi-Agent (MA-LESSA)
deployments, enveloping radio environments with several CRs
performing intelligent spectrum sensing and access. We propose novel neighbor discovery and channel access rank allocation schemes that enable the CRs to collaborate and capitalize
on spectral resources left unused by the multiple LUs in the network. We implement MA-LESSA on the DARPA Spectrum
Collaboration Challenge (SC2) platform, manifesting superior performance over competitors in a real-world TDWR-UNII
WLAN emulation [17]. Finally, we demonstrate the implementation feasibility of MA-LESSA in a network of ESP32 radios, and we illustrate the performance disparities between collaborative and opportunistic (non-cooperative or competitive) access through comparisons with algorithms in the multi-agent literature.

Related Work: We now discuss the most closely-related works in the state-of-the-art, summarized in Table I. Most prior algorithms for spectrum sensing and access operate under the assumption that the occupancy behavior of LUs is independent across both time and frequency [10]–[14], or exploit temporal correlation but fail to capitalize on frequency correlation [6]–[9]. These assumptions are not only impractical [16] but also imprudent because critical information aiding the accurate detection of white-spaces may be gleaned by exploiting the correlation in LUs' occupancy over both time and frequency, as done in this work.

Spectrum sensing algorithms exploiting both time-116 frequency correlation in LU occupancy are studied in [2]-[5]. Yet, the system detailed in [3] learns the time-frequency 118 LU occupancy correlation structure offline using pre-loaded 119 databases, which may be inefficient in non-stationary settings; 120 in contrast, we propose a concurrent learning and adaptation 121 framework in which CRs learn a time-frequency correlation 122 model of LUs' occupancy via an online Baum-Welch algo-123 rithm, and leverage this knowledge to concurrently optimize 124 spectrum sensing and access (under sensing limitations). On 125 the other hand, LESSA achieves performance superior to 126 model-free DQN [2], owing to a parametric time-frequency 127 Markov transition model. Contrasting our framework against 128 black-box Deep Learning models [4], [5], our approach cir-129 cumvents laborious data collection and pre-processing tasks, 130 thanks to online learning of the parametric time-frequency

correlation model underlying the LUs' occupancy 131 behavior.

In terms of the observation model, a noiseless spectrum 133 sensing setting is assumed in [3], which is unrealistic. In [6], 134 LUs' spectrum occupancy is estimated directly via energy 135 detection thereby ignoring errors in state estimation, while 136 we incorporate a multi-subcarrier access decision based on 137 the contemporary posterior belief probability distribution. 138 Although the DQN framework in [2] revolves around a 139 POMDP formulation, the uncertainty involved is assumed to 140 be only due to sensing restrictions by the CR, while making no 141 claims about system operations in noisy settings. Differently 142 from these works, we assume a Hidden Markov Model (HMM) 143 formulation in which the true LU occupancy states are hidden 144 behind noisy observations at a CR's spectrum sensor. Hence, 145 partial observability in our formulation is due simultaneously to channel sensing restrictions, a noisy observation model, and 147 unknown LU occupancy dynamics.

All the above works fail to provide a mechanism to manage the trade-off between CRs' network throughput and LUs' interference; in contrast, LESSA enables this feature through a weighted reward metric that favors CRs' throughput and penalizes LUs' interference. Unlike non-adaptive sensing strategies [4], [5], [9], [12]–[14], our solution adapts the sensing action in each time-step to more effectively cope with spectrum sensing constraints, driven by transition model estimates and reward/penalty feedback.

Finally, analyzing the state-of-the-art in the multi-agent distributed CR domain, we find both collaborative [5], [6], [8], 159 [11]–[14] as well as opportunistic [11] schemes for channel 160 sensing and access. Drawing a contrast between our contributions and the systems detailed in these works, the authors 162 in [8] make independence assumptions during a projection 163 approximation to a lower-dimensional space; [13], [14] assume 164 a time-frequency independence structure in LUs' occupancy, 165 and employ energy detection at the CRs, i.e., no adaptive 166 sensing and more importantly, no policy optimization; [12] 167 focuses primarily on data aggregation strategies within the 168 ensemble; [6] proposes a multi-agent Temporal Difference 169 (TD) SARSA with Linear Function Approximation (LFA), but 170 fails to detail neighbor discovery and channel access order 171 allocation schemes, proposed in this paper; [11] details a 172

251

173 collaborative scheme (greedy learning under pre-allocation) and an opportunistic one (g-statistics with ACKs), under the 175 assumption of time-frequency independence in LUs' occupancy behavior; additionally, the opportunistic scheme in [11] 177 relies on ACKs as a feedback mechanism to gauge the utility an access decision, which imbibes unnecessary lag into the model; in contrast, our framework employs a threshold-based decision heuristic involving the posterior belief probability to aluate the reward obtained from the executed access action: addition to displaying superior performance, as illustrated Section IV, this mechanism is easier to implement in real-184 world settings, as we demonstrate by realizing our solution the DARPA SC2 emulator [18] and on an ad-hoc ESP32 186 network [19].

- We develop a LEarning-based framework for Spectrum Sensing and Access (LESSA) in a radio environment with LUs exhibiting time- and frequency- Markovian correlation in their occupancy behavior, and a CR attempting to detect and access unused spectral resources - under a noisy observation model with sensing restrictions.
- In Section III-A, we develop an online Baum-Welch algorithm [20] to learn the LUs' occupancy correlation model.
- In Section III-B, we concurrently leverage the learned model in a randomized PBVI algorithm known as PERSEUS [21] to devise an approximately optimal spectrum sensing and access policy; we alleviate its computational complexity by introducing fragmentation, belief update simplification heuristics via Hamming distance state filters and Monte-Carlo based methods.
- In single-agent settings, we demonstrate the superior performance of LESSA relative to relevant algorithms in the state-of-the-art (Section IV). Additionally, through computational time complexity bench-marking, we prove the enhanced scalability of our solution.
- In Section V, we extend LESSA to distributed Multi-Agent (MA-LESSA) deployments: adapting the Multiband Directional Neighbor Discovery scheme described in [22] to distributed multi-agent CR deployments, we propose a novel neighbor discovery heuristic centered around RSSI thresholding; inspired by cluster fallback mechanisms (leader selection, broker failover, masterslave auto-configuration, and data replication) involved in Message Oriented Middleware [23], we propose a channel access rank allocation technique centered around a quorum-based preferential ballot algorithm. On this front, we demonstrate improved performance over both collaborative and opportunistic distributed multi-agent state-ofthe-art; also, we exemplify its implementation feasibility on an ad-hoc WLAN testbed of ESP32 radios [19], [24].
- Finally, for multi-agent evaluations, we retrofit our proposed solution into the DARPA SC2 BAM! Wireless radio [25] to emulate its operations during the Active Incumbent scenario (TDWR-UNII WLAN) [17], and prove superior scoring performance over competing strategies [26]–[30]. We also perform computational

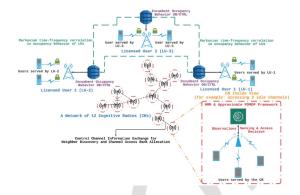

Fig. 1. The radio ecosystem under analysis: An exemplification of the system model detailed in Section II-A with $J_L=3$ and $J_C=12$: we first study deployments with $J_C=1$ before extending our analyses to multi-agent

time complexity analyses of our neighbor discovery 231 and channel access rank allocation heuristics in emu- 232 lations of highly-mobile real-world disaster relief (SC2 233 Payline [31]) and military deployment scenarios (SC2 234 Alleys of Austin [32]).

The rest of this paper is organized as follows: Section II 236 details the system model: Section III describes our algorith- 237 mic solutions; Section IV presents numerical evaluations for 238 the single-agent case; Section V extends LESSA to a dis 239 ributed multi agent setup, with numerical evaluations; finally, 240 Section VI provides concluding remarks.

II. SYSTEM MODEL

A. Signal Model

We consider a licensed network of J_L LUs, and J_C CRs ²⁴⁴ attempting to exploit portions of the spectrum left unused by 245 these LUs – as illustrated in Fig. 1. In Sections II, III, and IV, 246 we focus on the single-agent case ($J_C = 1$); the multi-agent ²⁴⁷ extension ($J_C>1$) is discussed in Section V. The spectrum of ²⁴⁸ interest is discretized into K subcarriers of bandwidth W. The 249 frequency-domain signal received at the CR's spectrum sensor 250 in time-slot t at subcarrier k is

$$Y_k(t) = \sum_{j=1}^{J_L} H_{j,k}(t) X_{j,k}(t) + V_k(t),$$
 (1) 252

where $X_{j,k}(t)$ is the frequency-domain signal of LU 253 $j \in \{1, \ldots, J_L\}$ on subcarrier $k \in \{1, \ldots, K\}$, with $X_{i,k}(t) = 0$ 254 if LU j is idle on subcarrier k; $H_{j,k}(t)$ denotes the channel on 255 subcarrier k between LU j and the CR; and $V_k(t) \sim \mathcal{CN}(0, \sigma_V^2)$ 256 denotes Gaussian noise with variance σ_V^2 , i.i.d across time 257 and subcarriers. We assume an Orthogonal Frequency Division 258 Multiple Access (OFDMA) strategy among the LUs: letting 259 $j_{k,t}$ be the index of the LU that occupies subcarrier k in 260 time-slot t, $X_k(t) \triangleq X_{j_{k,t},k}(t)$ and $H_k(t) \triangleq H_{j_{k,t},k}(t)$, we can 261 rewrite (1) as

$$Y_k(t) = H_k(t)X_k(t) + V_k(t),$$
 (2) 263

where $X_k(t) = 0$ if subcarrier k is not occupied in time- 264 slot t. We model $H_k(t)$ as Rayleigh fading with variance 285 $\sigma_H^2: H_k(t) \sim \mathcal{CN}(0, \sigma_H^2)$, i.i.d across time and subcarriers.

267 B. Time-Frequency Occupancy Correlation Structure

The LU's signal on subcarrier k in time-slot t is modeled as

$$X_k(t) = \sqrt{P_T} B_k(t) S_k(t), \tag{3}$$

where P_T denotes the transmission power of the occupant LU; $B_k(t)$ represents the binary occupancy variable, with $B_k(t)=1$ if subcarrier k is occupied by a LU in time-274 slot t, and $B_k(t)=0$ otherwise; $S_k(t)$ is the transmitted symbol, i.i.d across time and subcarriers, modeled from a cer-276 tain constellation with $\mathbb{E}[|S_k|^2]=1$. Then, $H_k(t)X_k(t)=1$ as a zero-mean complex Gaussian random variable with 279 variance σ_H^2 . We denote the spectrum occupancy state in 280 time-slot t as

$$\vec{B}(t) = [B_1(t), B_2(t), B_3(t), \dots, B_K(t)]^\mathsf{T} \in \{0, 1\}^K.$$
 (4)

²⁸² We assume that spectrum occupancy is correlated across time ²⁸³ and subcarriers: LUs typically occupy a set of adjacent sub-²⁸⁴ carriers (frequency correlation), repeating similar motifs in ²⁸⁵ behavior over an extended period of time (temporal corre-²⁸⁶ lation) [16], [33], [34]. To capture temporal correlation, we ²⁸⁷ model the evolution of $\vec{B}(t)$ over time as a Markov process

$$\mathbb{P}\Big(\vec{B}(t+1)|\vec{B}(j), \forall j \le i\Big) = \mathbb{P}\Big(\vec{B}(t+1)|\vec{B}(t)\Big)
\triangleq P_B\Big(\vec{B}(t+1)|\vec{B}(t)\Big), (5)$$

with one-step transition probability $P_B(\vec{B}(t+1)|\vec{B}(t))$. Using the chain rule of conditional probability, we can further express it as

$$P_{B}\left(\vec{B}(t+1)|\vec{B}(t)\right) = \mathbb{P}\left(B_{1}(t+1)|\vec{B}(t)\right)$$

$$\prod_{k=2}^{K} \mathbb{P}\left(B_{k}(t+1)|\vec{B}_{1:k-1}(t+1), \vec{B}(t)\right), \tag{6}$$

where $\vec{B}_{1:k-1}(t+1)$ is the spectrum occupancy state in sub-296 carriers 1 to k-1 in time-slot t+1. We further assume a 297 Markovian structure across frequency,

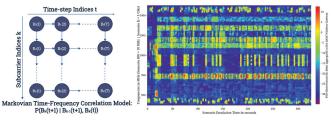

298
$$\mathbb{P}\Big(B_k(t+1)|\vec{B}_{1:k-1}(t+1),\vec{B}(t)\Big)$$
299
$$=\mathbb{P}\Big(B_k(t+1)|B_{k-1}(t+1),\vec{B}(t)\Big),$$

i.e., $B_k(t+1)$ is independent of the spectrum occupancy in the non-adjacent subcarriers $\vec{B}_{1:k-2}(t+1)$, when conditioned on $\vec{B}(t)$ and on the spectrum occupancy in the adjacent subcarrier $B_{k-1}(t+1)$. This assumption reflects the intuition that the state of the adjacent subcarrier k-1 ($B_{k-1}(t+1)$) more directly affects the state of subcarrier k than non-adjacent subcarriers 1 to k-2. Replacing this expression into (6), we finally obtain

$$P_{B}\left(\vec{B}(t+1)|\vec{B}(t)\right) = \mathbb{P}\left(B_{1}(t+1)|\vec{B}(t)\right)$$

$$\prod_{k=2}^{K} \mathbb{P}\left(B_{k}(t+1)|B_{k-1}(t+1), \vec{B}(t)\right). \tag{7}$$

We denote this model as *bottom-up frequency correlation*, since the state of subcarrier k depends on that of the adjacent

(a) The correlation model

(b) Active Incumbent PSD data

Fig. 2. Visualization of the LU occupancy time-frequency correlation structure (a); combined PSD plot of the occupancy behavior of a TDWR and competitors during the DARPA SC2 Active Incumbent scenario emulation (b).

lower subcarrier k-1, as opposed to the *top-down frequency* 312 *correlation* where it depends on that of the adjacent upper 313 subcarrier k+1. We remark that bottom-up and top-down 314 frequency correlation models can be used interchangeably: in 315 fact, replacing $\mathbb{P}(B_k(t+1)|B_{k-1}(t+1),\vec{B}(t)) = \mathbb{P}(B_{k-1}(t+3)$ 316 $\mathbb{P}(B_k(t+1),\vec{B}(t)) = \mathbb{P}(B_{k-1}(t+3)$ (Bayes' rule) in (7) and 317 simplifying, we obtain the top-down frequency correlation 318 model

$$P_{B}\Big(\vec{B}(t+1)|\vec{B}(t)\Big) = \mathbb{P}\Big(B_{K}(t+1)|\vec{B}(t)\Big)$$

$$\prod_{k=1}^{K-1} \mathbb{P}\Big(B_{k}(t+1)|B_{k+1}(t+1), \vec{B}(t)\Big), \tag{8} 321$$

so that the two models can be directly mapped to each other. 322 We now embed the bottom-up frequency correlation of (7) into 323 a parametric form. Expressing $\vec{B}(t) = [B_k(t), \vec{B}_{-k}(t)]$, where 324 $\vec{B}_{-k}(t)$ is the spectrum occupancy state in subcarriers other 325 than k in time-slot t, we define $\forall u, v, w \in \{0,1\}, 2 \le k \le K$ 326

Note that this parametric model assumes that $B_k(t+1)$ is 330 independent of $\vec{B}_{-k}(t)$, when conditioned on $(B_{k-1}(t+3), B_k(t))$: intuitively, the state of subcarrier k in time-slot 332 t+1 is most directly affected by the state on the same sub-333 carrier in the previous time-slot t, as shown in Fig. 2a. 334 In the following, we define the parameter vector $\vec{\theta} = 335$ $[p_{0,0}, p_{0,1}, p_{1,0}, p_{1,1}, q_0, q_1]$, and express the dependence of 336 the one-step transition model on $\vec{\theta}$ as $P_B(\vec{B}(t+1)|\vec{B}(t);\vec{\theta})$. 337

To experimentally validate the aforementioned parametric 338 time-frequency correlation model, we performed a Bayesian 339 Information Criterion (BIC) evaluation [35] on a dataset 340 of Power Spectral Density (PSD) measurements from the 341 DARPA SC2 Active Incumbent scenario emulation [17], 342 depicted in Fig. 2b. This scenario constitutes a Terminal 343 Doppler Weather Radar (TDWR) station, and several competitor CR networks [29], [30] (including our Purdue 345 BAM! Wireless [25]) of Unlicensed National Information 346 Infrastructure (UNII: 5GHz WLAN) Wi-Fi nodes. We define 347 the BIC metric as BIC = $\Gamma \cdot \ln \nu - 2 \ln \mathbb{P}(\mathbf{B}|\vec{\theta}^*)$, where ν is 348 the sample size, Γ is the number of model parameters (6 in the 349

350 proposed parametric model), B is the time-frequency binary occupancy matrix from the dataset, and $\vec{\theta}^*$ is the model param-352 eter vector estimated from the dataset of PSD measurements, 353 using the Baum-Welch algorithm detailed in Section III-A. We employed a 70-30 training-test split to evaluate this met-355 ric, i.e., the occupancy data collected during the first 70% of the 330 seconds of scenario emulation is used to estimate the model parameters, while the remaining 30% is dedicated to the BIC evaluation. The parametric bottom-up time-frequency 359 correlation model yields a BIC of 71.872, the best compared other state-of-the-art models: time-frequency independence 361 (98.840) [10]–[14]; time-only correlation (95.231) [6]–[9]; 362 frequency-only correlation (76.879); notably, the top-down 363 frequency correlation model, using a similar parameterization 364 of (9), yields a similar BIC metric of 74.207 (the slightly 365 different value is due to the parametric structure). This eval-366 uation reveals that exploiting frequency correlation is more 367 important than time correlation – and not surprisingly, exploit-368 ing both provides a better fit to the dataset. This assessment validates our conjecture that LUs in real-world deployments 370 exhibit prominent spectrum occupancy patterns across both time and frequency, exploited by LESSA. Moreover, it fur-372 ther corroborates our previous observation that bottom-up and 373 top-down correlation models can be used interchangeably.

374 C. Channel Sensing Model

The CR attempts to detect white-spaces and access them to deliver its network flows. Due to constraints on energy-efficiency and sensing/data aggregation times [14], it can sense a maximum of κ subcarriers in a time-slot, with $1 \leq \kappa \leq K$. The Let $\mathcal{K}_t \subseteq \{1,2,\ldots,K\}$ be the set of subcarriers sensed by the CR at time t, with $|\mathcal{K}_t| \leq \kappa$. This selection is dictated by a sensing policy, described in Section II-D. After sensing the subcarriers listed in \mathcal{K}_t , the observation vector $\vec{Y}(t) = [Y_k(t)]_{k \in \mathcal{K}_t}$ is collected, with $Y_k(t)$ given in (2). Owing to (2), the i.i.d. assumptions on the noise $V_k(t)$, the transmitted symbols $S_k(t)$, and the frequency domain subcarriers $H_k(t)$, the probability density function (pdf) of $\vec{Y}(t)$ conditioned on $\vec{B}(t)$ and \mathcal{K}_t is given by

$$f\left(\vec{Y}(t)|\vec{B}(t), \mathcal{K}_t\right) = \prod_{k \in \mathcal{K}_t} f(Y_k(t)|B_k(t)), \text{ where}$$

$$Y_k(t)|B_k(t) \sim \mathcal{CN}\left(0, \sigma_H^2 P_T B_k(t) + \sigma_V^2\right). \tag{10}$$

390 D. POMDP Formulation and Spectrum Access

POMDPs model the repeated, sequential interactions of an agent tasked with maximizing its reward, with a stochastic environment, in which the agent has only access to noisy observations. We now describe the POMDP operation, whose process flow is illustrated in Fig. 3 (the multi-agent features, shown in green, will be discussed in Section V).

Prior to gathering spectrum measurements in time-slot t, the POMDP state is given by the prior belief β_t , i.e., the probability distribution of the unknown spectrum occupancy state $\vec{B}(t)$, given the history of measurements obtained by the CR's spectrum sensor up to, but not including, time-slot t. Given β_t , the CR chooses a sensing action according to a sensing policy

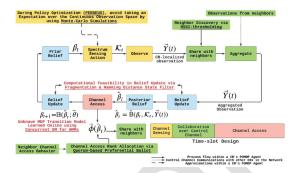

Fig. 3. The POMDP process flow as discussed in Section II-D – with neighbor discovery, channel access rank allocation, and time-slot design (shown in green) discussed in our multi-agent deployment analysis (Section V).

 π , $\mathcal{K}_t = \pi(\beta_t) \in \mathcal{A}$, where \mathcal{A} is the spectrum sensing space, 403 i.e., all possible combinations in which κ subcarriers are chosen to be sensed in a time-slot (discussed in Section II-C); 405 the CR then senses the subcarriers in \mathcal{K}_t , observes $\vec{Y}(t)$, and 406 computes the posterior belief of $\vec{B}(t)$ using Bayes' rule, as

$$\hat{\beta}_{t}(\vec{B}) = \mathbb{P}\Big(\vec{B}(t) = \vec{B}|\beta_{t}, \mathcal{K}_{t}, \vec{Y}(t)\Big)$$

$$= \frac{f\Big(\vec{Y}(t)|\vec{B}, \mathcal{K}_{t}\Big)\beta_{t}(\vec{B})}{\sum_{\vec{B}' \in \{0,1\}^{K}} f\Big(\vec{Y}(t)|\vec{B}', \mathcal{K}_{t}\Big)\beta_{t}(\vec{B}')}.$$
(11) 40:

Given $\hat{\beta}_t$, the CR then makes channel access decisions 410 $\vec{\phi} \in \{0,1\}^K$, where $\phi_k = 1$ denotes the CR's decision to access 411 the kth subcarrier, otherwise $\phi_k = 0$. We design $\vec{\phi}$ based on 412 the reward metric

$$R(\vec{\phi}, \vec{B}(t)) = \sum_{k=1}^{K} (1 - B_k(t))\phi_k - \lambda B_k(t)\phi_k.$$
 (12) 41

Since $\vec{B}(t)$ is unknown, we compute its expectation based on the posterior belief $\hat{\beta}_t$ as

$$R\left(\vec{\phi}, \hat{\beta}_{t}\right) = \mathbb{E}\left[R\left(\vec{\phi}, \vec{B}(t)\right) | \vec{\phi}, \hat{\beta}_{t}\right]$$

$$= \sum_{k=1}^{K} \left(1 - \hat{\beta}_{t,k}\right) \phi_{k} - \lambda \hat{\beta}_{t,k} \phi_{k}, \qquad (13) \text{ 418}$$

where $\hat{\beta}_{t,k} = \sum_{\vec{B} \in \{0,1\}^K: B_k = 1} \hat{\beta}_t(\vec{B})$ is the posterior probability that subcarrier k is occupied by a LU. Note that, if 420 the CR uses the kth subcarrier ($\phi_k(t) = 1$), it accrues a 421 reward of 1 if the subcarrier is truly idle (with posterior 422 probability $1 - \hat{\beta}_{t,k}$), and a penalty of $\lambda \geq 0$ if it is occupied (with posterior probability $\hat{\beta}_{t,k}$); it accrues no reward 424 for not using a channel. Hence, (13) balances a trade-off 425 between maximizing the CR's throughput (CR's transmissions on idle subcarriers), and minimizing the interference 427 to the LUs (CR's transmissions on occupied ones); λ regulates such trade-off. The channel access decision is obtained 429 as $\vec{\phi}^*(\hat{\beta}_t) = \arg\max_{\vec{\phi} \in \{0,1\}^K} R(\vec{\phi}, \hat{\beta}_t)$, yielding

$$\phi_k^*(\hat{\beta}_t) = \mathcal{I}[\hat{\beta}_{t,k} \le (1+\lambda)^{-1}], \ \forall k = 1,\dots,K, \quad (14)$$
 431

 $_{432}$ where $\mathcal{I}[\;\cdot\;]$ is the indicator function, yielding the optimized $_{433}$ reward

434
$$R^*(\hat{\beta}_t) = \max_{\vec{\phi} \in \{0,1\}^K} R(\vec{\phi}, \hat{\beta}_t)$$

$$= \sum_{k=1}^K \max \{1 - (1+\lambda)\hat{\beta}_{t,k}, 0\}. \tag{15}$$

 $_{436}$ In other words, if the CR is confident that the kth subcar- $_{437}$ rier is idle $(\hat{\beta}_{t,k} < \frac{1}{1+\lambda})$, it accesses it; otherwise, it remains $_{438}$ idle. The confidence level $\frac{1}{1+\lambda}$ is regulated by the penalty $_{439}$ parameter λ .

After accessing the subcarriers based on the access decision $\phi_k^*(\hat{\beta}_t)$, the CR then updates the prior belief for the next time-442 slot t+1 based on the one-step transition model,

$$\beta_{t+1}(\vec{B}) = \sum_{\vec{B}' \in \{0,1\}^K} P_B\left(\vec{B}|\vec{B}'; \vec{\theta}\right) \hat{\beta}_t\left(\vec{B}'\right), \quad (16)$$

and the process is repeated over time. Let

$$\hat{\beta}_t = \hat{\mathbb{B}}(\beta_t, \mathcal{K}_t, \vec{Y}(t)), \quad \beta_{t+1} = \mathbb{B}(\hat{\beta}_t; \vec{\theta})$$
 (17)

denote the functions that map the prior belief β_t to the pos-447 terior belief $\hat{\beta}_t$, and the latter to the next prior belief β_{t+1} 448 (see Eqs. (11) and (16)). The goal is to devise a spectrum 449 sensing policy (the spectrum access policy is given in (14)) to 450 maximize the infinite-horizon discounted reward

$$V^{\pi}(\beta) = \mathbb{E}_{\pi} \left[\sum_{t=1}^{\infty} \gamma^{t} R^{*} (\hat{\beta}_{t}) \middle| \beta_{0} = \beta \right], \tag{18}$$

where $0<\gamma<1$ is the discount factor, $\beta_0=\beta$ (e.g., uniform) is the initial belief, and $\hat{\beta}_t$ is the posterior belief induced by the policy $\mathcal{K}_t=\pi(\beta_t)$ and the observation vector $\vec{Y}(t)$ via $\hat{\beta}_t=1$ 0 $\hat{\mathbb{B}}(\beta_t,\mathcal{K}_t,\vec{Y}(t))$. The maximization problem is then stated as

$$\pi^* = \operatorname*{max}_{\pi} V^{\pi}(\beta), \tag{19}$$

 $_{457}$ yielding the optimal value $V^*(\beta)$ under the optimal spectrum $_{458}$ sensing policy $\pi^*.$ In principle, $V^*(\beta)$ can be determined via $_{459}$ the value iteration algorithm $V_{i+1}=\mathcal{H}(V_i),$ initialized as $_{460}$ $V_0(\beta)=0,$ which converges to V^* as $i\to\infty$ [36]. Here, \mathcal{H} $_{461}$ is the Bellman's operator, defined as $\forall\beta$

$$V_{i+1}(\beta) = \max_{\mathcal{K} \in \mathcal{A}} \mathbb{E}_{\vec{Y} \mid \vec{B} \sim \beta, \mathcal{K}}$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

$$R^* \left(\hat{\mathbb{B}} \left(\beta, \mathcal{K}, \vec{Y} \right) \right)$$

We term (20) the *backup* operation, which in exact value teration should be solved for every belief β in the probability simplex. Intuitively, $V_i(\beta)$ and $V_{i+1}(\beta)$ represent the optimal finite horizon (of duration i and i+1, respectively) discounted values starting from belief β . To determine V_{i+1} from

 V_i , after choosing the spectrum sensing set \mathcal{K} and observing \vec{Y} , the posterior belief is updated as $\hat{\beta} = \hat{\mathbb{B}}(\beta,\mathcal{K},\vec{Y})$, 471 the reward $R^*(\hat{\beta})$ is accrued, the next prior belief is updated as $\beta_{next} = \mathbb{B}(\hat{\beta};\vec{\theta})$, so that $\gamma\,V_i(\beta_{next})$ is the discounted 473 future value accrued; the expectation is then taken with 474 respect to \vec{Y} , whereas the maximization over $\mathcal{K} \in \mathcal{A}$ yields the 475 optimal spectrum sensing action that maximizes the expected 476 reward plus discounted future value. Yet, this direct approach 477 is not applicable to our settings: 1) the transition model 478 $P_B(\vec{B}(t+1)|\vec{B}(t);\vec{\theta})$ needed in (16) to update the prior 479 β_{t+1} is unknown; 2) as the number of subcarriers of interest 480 increases, the number of states of the underlying MDP scales 481 exponentially, resulting in a high-dimensional belief space and 482 high complexity. To address these two challenges:

- We incorporate an HMM EM estimator, i.e., the Baum- 484 Welch algorithm, to learn the parameter vector $\vec{\theta}$ that 485 defines the transition model $P_B(\vec{B}(t+1)|\vec{B}(t);\vec{\theta})$, while 486 concurrently solving for the sensing and access policy. 487 This is developed in Section III-A.
- We embed a low-complexity approximate PBVI algorithm known as PERSEUS [21], and embed it with fragmentation (into independent subsets of highly-correlated
 subcarriers), belief update simplification heuristics
 (Hamming distance state filters), and Monte-Carlo methods, developed in Section III-B.

III. LESSA ALGORITHMS

In this section, we propose a Baum-Welch algorithm to 496 estimate the parameter vector $\vec{\theta}$ that defines the Markov time-497 frequency correlation model. In Section III-B, we then use the 498 estimated model in a randomized PBVI algorithm known as 499 PERSEUS [21] to determine an approximately optimal sensing 500 policy. Crucially, these algorithms are executed concurrently 501 – a key feature to enable adaptation in non-stationary settings. 502

A. Occupancy Correlation Structure Estimation

Let τ be the learning period of the parameter estimation 504 algorithm. Let $\mathbf{B} = [\vec{B}(t)]_{t=1}^{\tau}$ be the unknown sequence of 505 states and $\mathbf{Y} = [\vec{Y}(t)]_{t=1}^{\tau}$ be the sequence of observations 506 made at the CR's spectrum sensor from t=1 to $t=\tau$, 507 based on a generic spectrum sensing policy. We formulate the 508 Maximum Likelihood Estimation (MLE) problem to estimate 509 the vector $\vec{\theta}$ that defines the LU occupancy time-frequency 510 correlation structure (detailed in Section II-B) as

$$\vec{\theta}^* = \arg\max_{\vec{\theta}} \log \left(\sum_{\mathbf{B}} \mathbb{P}(\mathbf{B}|\vec{\theta}) f(\mathbf{Y}|\mathbf{B}, \mathcal{K}) \right).$$
 (21) 512

Note that $f(\mathbf{Y}|\mathbf{B},\mathcal{K}) = \prod_{t=1}^{\tau} f(\vec{Y}(t)|\vec{B}(t),\mathcal{K}_t)$ is the obsersation pdf conditional on the states, given by (10), whereas states $\mathbb{P}(\mathbf{B}|\vec{\theta})$ can be expressed using the one-step parametric transition model as $\mathbb{P}(\mathbf{B}|\vec{\theta}) = \mathbb{P}(\vec{B}(1)) \prod_{t=2}^{\tau} P_B(\vec{B}(t)|\vec{B}(t-1);\vec{\theta})$. States of the MLE problem using the Baum-Welch algorithm, states and EM algorithm for HMMs [37] that estimates $\vec{\theta}^{(i)}$ (i denotes the iteration index) by iterating through the E- and M- steps: states $\vec{\theta}^{(i)}$, the E-step computes

$$Q\!\left(\vec{\theta}|\vec{\theta}^{(i)}\right) = \mathbb{E}_{\mathbf{B}|\mathbf{Y},\vec{\theta}^{(i)}}\!\left[\log\left(\mathbb{P}\!\left(\mathbf{B}|\vec{\theta}\right)\!f(\mathbf{Y}|\mathbf{B},\mathcal{K})\right)\right]; \ (22) \ _{521}$$

522 afterwards, the M-step updates the estimate of $\vec{\theta}$ as

$$\vec{\theta}^{(i+1)} = \underset{\vec{\theta}}{\arg\max} \ Q\left(\vec{\theta}|\vec{\theta}^{(i)}\right). \tag{23}$$

⁵²⁴ Specifically, using the Markovian correlation structure, and neglecting additive terms independent of the optimization parameter $\vec{\theta}$ (indicated as \propto), the E-step can be rewritten as

530 where we have defined

531
$$A_w^{(i)}(b) \triangleq \sum_{t=2}^{r} \mathbb{P}\Big(B_1(t) = b, B_1(t-1) = w | \mathbf{Y}, \vec{\theta}^{(i)}\Big),$$
532 $B_{u,v}^{(i)}(b) \triangleq \sum_{t=2}^{\tau} \sum_{k=2}^{K} \mathbb{P}\Big(B_k(t) = b, B_{k-1}(t) = u, B_k(t-1)\Big)$
533 $\mathbb{P}\Big(B_k(t) = b, B_{k-1}(t) = u, B_k(t-1)\Big)$

computed using the Forward-Backward algorithm [20]; the Msss step can then be optimized in closed-form as

$$\qquad \qquad \mathbf{p}_{w}^{(i+1)} = \frac{A_{w}^{(i)}(1)}{A_{w}^{(i)}(0) + A_{w}^{(i)}(1)}, \ p_{u,v}^{(i+1)} = \frac{B_{u,v}^{(i)}(1)}{B_{u,v}^{(i)}(0) + B_{u,v}^{(i)}(1)}.$$

The computational time complexity of the Baum-Welch algorithm is $O(\tau K \, \tilde{T})$ [20], where \tilde{T} is the number of iterations until convergence, which depends on the consistency of spectrum occupancy measurements, driven by our observation model and the CR's sensing limitations.

543 B. The PERSEUS Algorithm

LESSA solves for the spectrum sensing (and access, based on the reward maximization detailed in Section II-D) policy in 546 parallel with the parameter estimation algorithm, employing 547 its published iterative transition model estimates, until both 548 algorithms converge. We use PERSEUS [21] to devise an 549 approximately optimal sensing policy, primarily motivated by 550 the following rationale. Unlike the Exhaustive Enumeration 551 and the Witness algorithms in [36], PERSEUS does not 552 perform the backup operation (20) exhaustively on every 553 reachable belief point; instead, it backs-up only on a smaller 554 subset of reachable belief points, and exploits this backup operation to improve the value of other reachable belief points, achieve faster convergence; and instead of computing belief 557 distances as in the PBVI algorithm [38], it computes a finite '-dimensional set of reachable beliefs \mathcal{B} through an initial exploration phase, to balance computational complexity with accuracy (larger $U \Rightarrow$ improved accuracy but larger computational burden).

Despite being an approximate POMDP method which alleviates the computational overhead associated with the backup operation, PERSEUS applied to the spectrum sensing problem still possesses computational intractability challenges due to the high-dimensional spectrum occupancy state $\vec{B} \in \{0,1\}^K$ scale continuous observation space: the computational cost scales exponentially with the number of subcarriers K. To alleviate these challenges, we embed PERSEUS with three novel low-complexity enhancements.

1) In updating the prior belief as in (16), we avoid 571 iterating over all possible $\vec{B}' \in \{0,1\}^K$ by con-572 sidering only those state transitions that involve a 573 Hamming distance of at most $\delta \in \{1,2,\ldots,K\}$ subcar-574 riers between two consecutive state vectors $\vec{B}(t)$ and 575 $\vec{B}(t+1)$. This is practical because spectrum occupancy of LUs typically varies slowly over time, slower 577 than the processing dynamics of the POMDP agent. Let 578 $\mathcal{B}_{\delta}(\vec{B}) \equiv \{\vec{B}' \in \{0,1\}^K : \zeta(\vec{B},\vec{B}') \leq \delta\}$ be the set of 579 spectrum occupancy states with Hamming distance (ζ) 580 at most δ from state \vec{B} . The next prior belief is then 581 approximated as

$$\beta_{t+1} \approx \tilde{\mathbb{B}}\left(\hat{\beta}_{t}, \vec{\theta}\right), \text{ where } \text{ Move the equation number (24) here }$$

$$\beta_{t+1}(\vec{B}) = \frac{\sum_{\vec{B}' \in \mathcal{B}_{\delta}\left(\vec{B}\right)} P_{B}\left(\vec{B}|\vec{B}'; \vec{\theta}\right) \hat{\beta}_{t}\left(\vec{B}'\right)}{\sum_{\vec{B}''} \sum_{\vec{B}' \in \mathcal{B}_{\delta}\left(\vec{B}''\right)} P_{B}\left(\vec{B}''|\vec{B}'; \vec{\theta}\right) \hat{\beta}_{t}\left(\vec{B}'\right)},$$
58
$$(24)$$
58

where the normalization ensures that β_{t+1} is a probability distribution that sums to one.

- We use a fragmentation technique to partition the set 588 of K subcarriers into independent smaller sets of adja- 589 cent subcarriers; we then run PERSEUS independently 590 on each one of these fragments, concurrently and in 591 parallel, by employing multi-threading capabilities in 592 software frameworks. For example, a radio environment 593 with 18 subcarriers with a sensing constraint of 6 sub- 594 carriers per time-slot is fragmented into 3 independent 595 fragments, each comprising 6 subcarriers correlated by 596 the occupancy behavior of the corresponding LUs, and 597 a sensing constraint of 2 subcarriers per time-slot. This 598 fragmentation is practical because in a radio environ- 599 ment with multiple LUs, each LU is typically restricted 600 to a portion (a set of adjacent frequency bands) of the 601 spectrum, either by design or by bureaucracy. We let 602 K' be the number of subcarriers, κ' be the sensing 603 restriction in each of these fragments.
- 3) We avoid the expectation with respect to the continuous observation vector in the backup operation (20) by using a Monte-Carlo method: we generate N independent realizations of $\vec{Y}|\vec{B},\mathcal{K}$, based on the observation model (10); we then compute the argument of the expectation with respect to each of these realizations, followed by a sample average. As $N \to \infty$, this sample average 611 converges to the conditional expectation in the backup 612 operation.

The resulting *Monte-Carlo Fragmented PERSEUS* 614 with Hamming distance-based belief update is shown in 615 Algorithm 1 (run in parallel on each fragment of spectrum), 616

Algorithm 1 Monte-Carlo Fragmented PERSEUS With Hamming Distance State Filters

Input: Parameters $\vec{\theta}$; K' subcarriers, Fragment sensing limit κ' ; Observation model (10); Target accuracy $\epsilon > 0$; Belief space size U; **Output:** Set of hyperplanes and spectrum sensing actions $\{(\vec{\alpha}^u, \mathcal{K}^u) : u = 1, \dots, U\}$ per spectrum fragment. 1: Determine the set of reachable beliefs $\tilde{\mathcal{B}} \equiv \{\beta_u : u =$ 2: Initialization: Hyperplanes $\vec{\alpha}_0^u = \mathbf{0}, \forall u$; actions $\mathcal{K}_0^u = \emptyset, \forall u$; iteration i = -1; $V_0(\beta) = 0$, $V_{-1}(\beta) = -\infty$; while $|V_{i+1}(\beta) - V_i(\beta)| > \epsilon, \exists \beta \in \mathcal{B}$ do $i \leftarrow i+1; \quad \tilde{\mathcal{U}} \longleftarrow \{1, \dots, U\};$ ▷ Start new iteration 5: while $\tilde{\mathcal{U}} \neq \{\cdot\}$ do \triangleright Improve all points in $\tilde{\mathcal{U}}$ Pick u randomly from $\tilde{\mathcal{U}}$, and β_u from $\tilde{\mathcal{B}}$; $\tilde{\mathcal{U}} \leftarrow \tilde{\mathcal{U}} \setminus \{u\}$; For each $K \in A$, compute hyperplane ξ_K^u : $\xi_{\mathcal{K}}^{u}(\vec{B}) = \frac{1}{N} \sum_{n=1}^{N} \left[R(\vec{\phi}^{*}(\hat{\mathbb{B}}(\beta_{u},\mathcal{K},\vec{Y}_{n})),\vec{B}) + \frac{\text{Move ** to this next line;}}{\text{Finally proper alignment}} \right]$ $\gamma \cdot \sum_{\vec{B}'} P_{B}(\vec{B}'|\vec{B};\vec{\theta}) \xi_{\mathcal{K},n}^{u}(\vec{B}') \right], \text{ where}$ $\vec{Y}_n \sim f(\cdot | \vec{B}, \mathcal{K})$ i.i.d. over n = 1, ..., N (Eq. (10)), and $\xi_{\mathcal{K},n}^{u} = \underset{i}{\operatorname{arg max}} \langle \tilde{\mathbb{B}}(\hat{\mathbb{B}}(\beta_{u},\mathcal{K},\vec{Y}_{n})), \vec{\alpha}_{i}^{u'} \rangle$ 10: $\begin{aligned} &\zeta \mathcal{K}, n = \underset{\vec{\alpha}_{i}^{u'}, u' \in \{1, 2, \dots, |\tilde{\mathcal{B}}|\}}{\vec{\alpha}_{i}^{u'}, u' \in \{1, 2, \dots, |\tilde{\mathcal{B}}|\}} \\ &\mathcal{K}_{i+1}^{u} = \underset{\vec{\alpha}_{i+1}}{\arg\max}_{\mathcal{K} \in \mathcal{A}} \langle \beta_{u}, \xi_{\mathcal{K}}^{u} \rangle, \\ &\vec{\alpha}_{i+1}^{u} = \xi_{\mathcal{K}_{i+1}^{u}}^{u}, V_{i+1}(\beta_{u}) = \langle \beta_{u}, \vec{\alpha}_{i+1}^{u} \rangle; \end{aligned}$ 11: 12: $\forall u' \in \mathcal{U} \text{ do} \qquad \text{Remove unnecessary white spaces in line 15 of Alg if } \langle \beta_{u'}, \vec{\alpha}_{i+1}^u \rangle \geq V_i(\beta_{u'}) \text{ then}$ 13: 14 15 16 Return set of hyperplanes and associated spectrum sensing actions $\{(\vec{\alpha}^{*u}, \mathcal{K}^{*u}) \stackrel{\triangle}{=} (\vec{\alpha}_i^u, \mathcal{K}_i^u): u = 1, \dots, U\}.$

Line numbers are incorrect due to an overlap at numbers 7 and 8 here in Alg 1

617 described below. The key idea of PERSEUS is to exploit 618 the fact that the value function V_i generated by the backup 619 operation (20) is Piece-Wise Linear Convex (PWLC) [21], 620 hence it can be approximated by an U-dimensional set of 621 hyperplanes (each associated to a certain sensing action, Step 622 $\frac{20}{20}$) as

$$V(\beta_t) \approx \max_{u \in \{1, 2, \dots, U\}} \langle \beta_t, \vec{\alpha}^{*u} \rangle, \tag{25}$$

i.e., it is a PWLC function of β_t , where $\langle \beta, \vec{\alpha} \rangle = \sum_{\vec{B}} \beta(\vec{B}) \vec{\alpha}(\vec{B})$ denotes inner product, and $\{\vec{\alpha}^{*u} : u = 1, \dots, U\}$ is the set of hyperplane vectors. Letting u_t be the maximizing index in (25), the approximately optimal spectrum sensing action is \mathcal{K}^{*u_t} , associated with the maximizing hyperplane $\vec{\alpha}^{*u_t}$. The goal of PERSEUS is to determine such a set of hyperplanes and associated actions. With these, the CR then operates as follows: with the prior belief β_t at timesolution to the collects the observation $\vec{Y}(t)$, computes the posterior belief as $\hat{\beta}_t = \hat{\mathbb{B}}(\beta_t, \mathcal{K}_t, \vec{Y}(t))$, performs spectrum access as in (14), and updates the next prior belief as $\hat{\beta}_{t+1} = \mathbb{B}(\hat{\beta}_t; \vec{\theta})$, and so on.

To determine these hyperplanes and associated actions, PERSEUS is first preceded by an initial phase of explosion ration to determine a set of representative belief points $\tilde{\mathcal{B}}$,

by allowing the CR to randomly interact with the radio envi- 640 ronment (Step 1). With \mathcal{B} thus determined, the hyperplanes 641 and associated actions are computed iteratively through Steps 642 $\frac{6}{3-19}$, after initializing them in Step 2. At iteration i, start- 643 ing from the entire set of beliefs, i.e., all indices $\{1, \ldots, U\}$ 644 (Step 4), the algorithm selects one belief at random, $\beta_u \in \hat{\mathcal{B}}$ 645 (Step 6). For this belief point, it then performs the backup 646 operation similarly to (20), by searching through all possible 647 spectrum sensing actions (Step 7) to determine the optimal 648 one that maximizes the value (Step 11). The value of a cer- 649 tain spectrum sensing action \mathcal{K} is determined in Steps 8-10. To 650 understand these steps, it is helpful to note that $\xi_{\mathcal{K}}^u(\vec{B})$ is the value accrued starting from state \vec{B} and sensing action \mathcal{K} , so 652 that $\langle \beta_u, \xi_{\kappa}^u \rangle$ done in Step H represents an expectation with 653 respect to the belief β_u , i.e., the expected value of the sensing 654 action $\mathcal K$ from belief eta_u . $\xi^u_{\mathcal K}(ec B)$ is comprised of two components: the instantaneous reward $R(\vec{\phi}^*(\hat{\mathbb{B}}(\beta_u,\mathcal{K},\vec{Y}_n)),\vec{B})$ 656 accrued in state \vec{B} , after observing \vec{Y}_n and computing the 657 spectrum access decision as in (14); the discounted future 658 reward $\sum_{\vec{B}'} P_B(\vec{B}'|\vec{B};\vec{\theta}) \xi^u_{K,\vec{Y}_n}(\vec{B}')$, obtained by averaging 659 with respect to the one-step transition from \vec{B} to \vec{B}' ; here, $\xi^u_{K,n}$ is the hyperplane associated to the future value function, deter- 661 mined in Step 10 as the one that maximizes the value function 662 (with PWLC structure) based on the next prior belief, com- 663 puted via the Hamming distance-based method of (24). Finally, 664 $\xi_{\mathcal{K}}^{u}(\vec{B})$ is obtained by taking an expectation with respect to the 665 observations using the aforementioned Monte-Carlo method: 666 Step Θ generates N independent realizations of \vec{Y} given \vec{B} and \mathcal{K} , so that $1/N\sum_{n}[\cdot]$ in Step'8 converges to $\mathbb{E}_{\vec{Y}|\vec{B}|\mathcal{K}}[\cdot]$ as 668

Another key approximation of PERSEUS is to limit as much 670 as possible the number of backup operations of Steps 7-11 671 by adding Steps 12-17: here, the algorithm scans through 672 the set of unimproved belief points indexed by \mathcal{U} ; it then 673 checks whether the new hyperplane $lpha_{i+1}^u$ determined in the 674 backup operation improves the value of any remaining belief 675 points; if it does for belief $\beta_{n'}$ (Step 13), then this new hyperplane (and its associated sensing action) becomes the relevant 677 hyperplane (and the relevant sensing action) for this belief 678 point (Step 14), and u' is removed from \mathcal{U} (Step 15), so 679 that the backup operation is not done for $\beta_{n'}$ at iteration i. 680 These sequence of operations (random choice from \mathcal{U} , backup, 681 check for improvement and removal) are performed iteratively 682 until the set $\tilde{\mathcal{U}}$ is empty (Step 5): this constitutes a single 683 PERSEUS iteration. Multiple iterations are executed until the 684 value iteration updates converge (Step 3).

The computational time complexity of Algorithm 1 is $_{686}$ $O(\tilde{T}|\tilde{\mathcal{B}}|^22^{2K'})$ [21], where \tilde{T} denotes the number of iterations until convergence. Note here that incorporating Hamming $_{688}$ distance state filters to alleviate the computational intractability inherent in PERSEUS belief update further mitigates the $_{690}$ exponential dependence on the fragment size.

IV. NUMERICAL EVALUATIONS FOR LESSA

In this section, we evaluate numerically LESSA and compare it against state-of-the-art algorithms. The simulated radio environment constitutes $J_L=3\,$ LUs accessing a 2.88MHz 695

696 spectrum, discretized into K = 18 subcarriers, each of band-697 width of W = 160 kHz, and one CR, as illustrated in 698 Fig. 1. The 3 LUs access these 18 subcarriers according to 699 a time-frequency Markovian correlation structure defined in 700 Section II-B, with parameters $p_{0,0} = 0.1, p_{0,1} = p_{1,0} =$ 701 $0.3, p_{1.1} = 0.7, q_0 = 0.3, q_1 = 0.8$. LUs' and CR's transmit-702 ters and receivers are deployed randomly across an operational 703 region: the three LUs' transmitters are placed at positions (-225, 200)m, (225, 200)m and (0, -300)m, at a height of 705 40m; the corresponding LU receivers are stationary nodes, 706 placed randomly within a circular radius of 200m from the 707 respective LU's transmitter. The CR's transmitter is located at 708 position (0, 0)m at a height of 20m; the corresponding receiver 709 is at ground level, and moves along a randomly generated tra-710 jectory within a radius of 100m from the CR's transmitter. 711 As described below, we have also facilitated rate adaptation 712 at the CR based on the perceived SINR, which may vary with 713 time and channel indices. The CR is capable of sensing $\kappa = 6$ 714 subcarriers per time-slot.

For each transmitter (Tx, LU or CR) and receiver (Rx; the 716 intended one, or unintended, thus experiencing interference) pairs, we model the channel on the kth subcarrier as $\hbar_k =$ ₇₁₈ $\sqrt{\psi}\omega_k$, where ψ and $\omega_k\in\mathbb{C}$ encapsulate the large- and small-719 scale channel variations, respectively – with $\mathbb{E}[|\omega_k|^2] = 1$. 720 Given the angle of elevation between the Tx/Rx pair under consideration, $\chi \in (0, \frac{\pi}{2}]$, we generate the line-of-sight (LoS) 722 condition with probability $P_{\rm LoS}(\chi)=\frac{1}{1+z_1e^{-z_2(\chi-z_1)}}$ [39], 723 so that the non-LoS (NLoS) condition occurs with probability $P_{NLoS}(\chi) = 1 - P_{LoS}(\chi)$, where z_1, z_2 are parameters specific 725 to the propagation environment. Given the LoS or NLoS condition, and the distance d between Tx and Rx, we then generate 727 the large- and small-scale channel conditions as follows. If the 728 channel is LoS: the large-scale fading coefficient ψ is modeled 729 as $\psi_{\text{LoS}}(d) = \psi_0 d^{-\mu_L}$, where ψ_0 is the reference pathloss at 730 a distance of 1m from the Tx and $\mu_L \ge 2$ is the LoS pathloss rgi exponent; the small-scale fading coefficient ω_k is modeled as 732 a Rician with K-factor $\mathbb{K}(\chi) = f_1 e^{f_2 \chi}$, where f_1, f_2 are param-733 eters specific to the propagation environment. Conversely, if 734 the channel is NLoS: the large-scale fading coefficient ψ is modeled as $\psi_{\text{NLoS}}(d) = \iota \psi_0 d^{-\mu_N}$, where $\iota \in (0,1]$ is the addi-736 tional NLoS attenuation and $\mu_N \ge \mu_L$ is the NLoS pathloss rg exponent; the small-scale fading coefficient ω_k is modeled as Rayleigh distributed (i.e., Rician with K-factor $\mathbb{K}(\chi)=0$). Throughout the simulation, we use $\mu_L=2.0,\ \mu_N=2.8,\ \iota=0$ 740 $0.2,\ W=160\ \mathrm{kHz},\ f_1=1.0,\ f_2=0.0512,\ z_1=9.12,\ \mathrm{and}$ $z_{2} = 0.16$ [40].

With this channel model, the SINR between the ith transmitter (LU or CR) and its intended receiver on subcarrier k is given by

$$SINR_{k,i} = \frac{\left| h_{k,i,i} \right|^{2} P_{k,i}}{\sigma_{V}^{2} + \sum_{j \neq i} \left| h_{k,j,i} \right|^{2} P_{k,j}},$$

where $\hbar_{k,i,i}$ is the channel between the ith transmitter and its tended indented receiver, $P_{k,i}$ is the transmission power; σ_V^2 is the role noise power and $\sum_{j \neq i} |\hbar_{k,j,i}|^2 P_{k,j}$ is the contribution from the active interferers: $\hbar_{k,j,i}$ is the channel between the jth receiver, with transmission

power $P_{k,j}$ ($P_{k,j}=0$ if such transmitter is idle on sub- 751 carrier k). We can then define the link capacity for such 752 transmitter-receiver pair on subcarrier k as

$$C_{k,i} = W \log_2(1 + \operatorname{SINR}_{k,i}).$$

We assume that the LUs transmit with fixed transmission 755 rate of $\Phi_{\rm LU}=0.9{\rm Mbps}$ (per subcarrier), and thus incur outage 756 if SINR $<2^{\Phi_{\rm LU}/W}-1$. We now detail the choice of the transmission rate at the CR, $\Phi_{\rm CR}$. Assuming that the large-scale 758 fading coefficient ψ and the K-factor $\mathbb K$ are known throughout 759 the simulation period (since they represent large-scale parameters, they can be reliably estimated), the outage probability 761 for an interference-free link is given by [39]

Align the "=" with the "=" in the previous line
$$P_{\mathrm{out}}(\Phi_{\mathrm{CR}},\psi,\mathbb{K}) = \mathbb{P}\left(C_{k,i} < \Phi_{\mathrm{CR}}|\psi,\mathbb{K}\right)$$

$$= 1 - Q_1 \left(\sqrt{2\mathbb{K}}, \sqrt{\frac{2(\mathbb{K}+1)\sigma_V^2}{\psi P_T}} \left(2^{\frac{\Phi_{\mathrm{CR}}}{W}} - 1\right)\right),$$
 764

where Q_1 denotes the standard Marcum Q-function. Herein, 765 we select the rate for the CR as the one that maximizes the 766 expected throughput $\Phi_{\rm CR} \cdot [1-P_{\rm out}(\Phi_{\rm CR},\psi,\mathbb{K})]$, obtained 767 efficiently via a bisection method [41].

To evaluate the performance, we define the average CR's $_{769}$ throughput over T time-slots as

where $\Phi_{{\rm CR},k}(t)$ is the rate used by the CR on subcarrier k 773 in time-slot t, based on the rate adaptation scheme described 774 earlier, and $\vec{\phi}(t)$ denotes the spectrum access decision in time- 775 slot t; we define the LUs' throughput over the same T time- 776 slots, normalized by the number of transmissions as

$$C^{\text{LUs}} = \frac{\sum_{t=1}^{T} \sum_{k=1}^{K} \Phi_{\text{LU}} B_k(t) \mathcal{I} \left[\text{SINR}_{\text{LU},k}(t) \geq 2^{\frac{\Phi_{\text{LU}}}{W}} - 1 \right]}{\sum_{t=1}^{T} \sum_{k=1}^{K} B_k(t)}, \qquad (27)$$

where ${\rm SINR_{LU,}}_k(t)$ is the SINR of the occupying LU, computed based on the channel realizations as described earlier.

In Fig. 4a, we plot the Mean Square Error (MSE) of the 783 Baum-Welch algorithm versus the number of EM steps (i), 784 $\|\vec{\theta} - \hat{\vec{\theta}}^{(i)}\|_2^2$, averaged over multiple independent realizations. 785 The parameters are initialized as $p_{u,v} = 0.5, \forall u,v \in \{0,1\}$ 786 and $q_w = 0.5, w \in \{0,1\}$. We observe that the MSE decreases 787 over time, as the estimation progresses through the E- and 788 M-steps [20], and converges to an MSE value of 0.03 after 789 $\sim 5 \times 10^4$ iterations: this corresponds to an observation 790 and estimation period of 160s, considering a typical time-slot 791 duration of 3ms.

In Fig. 4(a), we also plot the convergence of the PERSEUS 793 algorithm, using a discount factor of $\gamma=0.9$ and a termination 794 threshold of $\epsilon=10^{-5}$, $\lambda=1$, for both cases in which it is 795 run concurrently with the Baum-Welch algorithm (red curve) 796

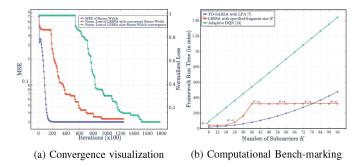

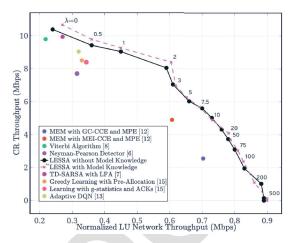

Fig. 4. MSE convergence of the Baum-Welch algorithm to estimate $\vec{\theta}$, and normalized loss incurred by Algorithm 1 (a); computational time complexity bench-marking of LESSA against state-of-the-art (b).

797 or after its convergence (green curve). To evaluate conver-798 gence, we use a normalized loss metric, defined as the loss of 799 utility (defined in (12)) with respect to an oracle that performs 800 spectrum access based on knowledge of the current occupancy state $\vec{B}(t)$, defined mathematically as

$$1 - \frac{R\left(\vec{\phi}^*\left(\hat{\beta}_t\right), \vec{B}(t)\right)}{\max_{\vec{\phi} \in \{0,1\}^K} R\left(\vec{\phi}, \vec{B}(t)\right)},$$

averaged out over time and multiple realizations, where $\vec{\phi}^*(\hat{\beta}_t)$ 804 is the spectrum access decision defined in (14), based on the posterior belief \hat{eta}_t generated in our POMDP formulation, and 806 $\max_{\vec{\phi} \in \{0,1\}^K} R(\vec{\phi}, \vec{B}(t))$ is the Oracle reward, which uses knowledge of $\vec{B}(t)$. We find that the concurrent method converges in approximately half the time of the non-concurrent 809 one. Remarkably, the normalized loss is around 5% after con-810 vergence, i.e., LESSA performs on par with an Oracle with 811 knowledge of the current spectrum occupancy – a significant 812 result considering the lack of a priori knowledge of the under-813 lying Markov transition model and the noisy and constrained 814 spectrum sensing environment. In addition, since the Oracle 815 performs better than the optimal POMDP policy, this result demonstrates that solving for the optimal POMDP policy (a 817 computationally intractable task) does not yield a tangible 818 boost in spectrum white-space detection, thereby legitimizing 819 the validity of the approximate POMDP approach proposed in 820 this paper. Fig. 4(b) plots the run time of LESSA as a function of the number of subcarriers, against TD-SARSA with LFA [6] and Adaptive DQN [2]. The algorithms are run on a 2×12 -core 823 Intel Xeon Gold 6126 @ 2.6GHz compute node with 192GB 824 RAM [42]: as the number of subcarriers increases, our solu-825 tion scales better yielding a more computationally tractable 826 performance relative to the other two, owing to fragmentation 827 and belief update simplification heuristics. Interestingly, for > 36 with fixed fragment size of K'=6, the run time of 829 LESSA flattens out: this is because LESSA is carried out in 830 parallel across all 6-subcarrier fragments.

In Fig. 5, we compare the performance of LESSA with state-832 of-the-art algorithms, in terms of the CR's network throughput achieved vis-à-vis LUs throughput, as defined in (26) and (27), 834 respectively. We note that LESSA covers the entire trade-off 835 region by varying the penalty weight λ in the reward metric

Evaluation of CR and LU network throughputs for different values of λ with rate adaptation at the CR and with/without correlation model foreknowledge - along with comparisons with the state-of-the-art.

of the POMDP. Generally, Fig. 5 depicts a trend of increasing CR throughput and decreasing LUs' throughput (due to 837 increased CR's interference), as the penalty λ is decreased. 838 Therefore, our framework provides a crucial practical tool in 839 CR MAC design: the ability to tune the trade-off between the 840 throughput obtained by the CR and the interference caused 841 by it to LU transmissions in the network. In contrast, the 842 other state-of-the-art algorithms do not offer such capabil- 843 ity, hence they attain a single point in the trade-off region. 844 By comparing LESSA with unknown model (learned with 845 the Baum-Welch algorithm) and LESSA with model known 846 a priori, we observe that prior knowledge of the model offers 847 a meagre 3.75% improvement in CR throughput for a given LU 848 network throughput, compared to the proposed online concur- 849 rent model estimation and policy solver strategy – a testament 850 to the accuracy of our estimator. Comparing LESSA with other 851 state-of-the-art schemes, we observe consistent improvement 852 in performance across the entire trade-off region. Specifically: 1 853

• Minimum Entropy Merging (MEM) with Greedy 854 Clustering (GC) based Channel Correlation Estimation 855 (CCE) and Markov Process Estimation (MPE) [3]: 856 Correlation Threshold 0.7; our solution offers a 115% 857 improvement over this strategy:

858

- MEM with Minimum Entropy Increment (MEI) based 859 CCE and MPE [3]: Correlation Threshold 0.7; our 860 solution achieves 40% better performance over this 861 strategy. In both GC and MEI implementations, our 862 improved performance is owed to the POMDP formu- 863 lation instead of an offline correlation-coefficient based 864 clustering scheme employed in their work;
- Imperfect HMM-MAP State Estimation [9]: it uses the 866 Viterbi algorithm; although [9] assumes time-only cor- 867 relation and no sensing restrictions, we extend it to our 868 setup to include *a priori* knowledge of the time-frequency 869

¹Unless otherwise stated, all these algorithms have a spectrum sensing restriction of $\kappa = 6$; implementation details can be found in the respective references; the percentage improvements are all referred to improvements in CR's throughput provided by LESSA under the same LUs' throughput achieved by the state-of-the-art scheme under consideration.

correlation model, and sensing restriction of $\kappa = 6$; our solution attains a 6% boost over this strategy owing to an adaptive sensing policy exploited in our solution as opposed to a fixed one in their system, despite the lack of a-priori model knowledge: a priori (in italics)

- Neyman-Pearson Detection [13]: it assumes timefrequency independence, and no channel sensing restrictions, an AND fusion rule across 300 samples, and threshold determination via a false alarm probability of 30%; our solution offers a 26% enhancement over this strategy, by leveraging the time-frequency LU occupancy dynamics in our framework in contrast to the independence assumptions made in their model, despite the sensing restrictions of our model;
- Temporal Difference Learning via SARSA with Linear Function Approximation (LFA) [6]: we use a belief update heuristic constant of 0.9, a discount factor of 0.9, a fixed exploration factor of 0.01, and a raw false alarm probability of 5%; our solution exhibits a 3% superior performance over this strategy, owing to our additional exploitation of LU occupancy correlation across frequency as opposed to a purely temporal strategy employed in their model;
- Greedy Learning under Pre-Allocation [11]: it uses a time-varying exploration factor, and assumes independence across both time and frequency;
- Learning with g-statistics and ACKs [11]: our solution achieves a 13% boost in performance over this strategy. In both implementations of [11], LESSA offers enhancements by leveraging the time-frequency correlation structure in LUs' spectrum occupancy, in contrast to the independence assumptions made in their model;
- Adaptive Deep Q-Networks [2]: with Experiential Replay (Memory Size 10^6), 2048 input neurons, 4096 neurons with ReLU activation functions in each of the 2 hidden layers of the neural network, a MSE cost function with an Adam optimizer, a fixed exploration factor of 0.1, a learning rate of 10^{-4} , a batch Size of 32; our solution offers a 9% improvement over this strategy, owing to a parametric time-frequency correlation model that captures the correlation in LU occupancy, as opposed to a model-free policy optimization scheme used in their system.

In Fig. 6(a), we plot the Cumulative Distribution Function 913 (CDF) of the reward $R(\vec{\phi}(t), \vec{B}(t))$, evaluated according to (13). We find that **LEMMA** achieves an average utility 914 of 11.98 per time-step, 125% higher than that achieved by 915 the MEM with GC based CCE and MPE algorithm from [3], 916 96% higher than that achieved by the MEM with MEI based 917 CCE and MPE algorithm from [3], and 42% higher than that 918 attained by the Neyman-Pearson Detector [13] (despite the 919 latter having no sensing restrictions). Compared to the Viterbi 920 algorithm [9] (= 11.78), our scheme achieves 2% higher utility 921 (= 11.98), thanks to an adaptive sensing strategy.

Finally, in Fig. 6(b), we illustrate the receiver operating 923 characteristic, i.e., the trade-off between false alarm prob- 924 ability $(P_{FA} = \mathbb{P}(\phi_k(t) = 0|B_k(t) = 0))$, i.e., the 925 subcarrier is incorrectly detected as occupied, and it is there- 926 fore not used by the CR) versus missed detection probability 927 $(P_{MD} = \mathbb{P}(\phi_k(t) = 1|B_k(t) = 1))$, i.e., the subcarrier is 928 incorrectly detected as idle, and it is therefore used by the 929 CR), averaged out over time-slots and subcarriers, for LESSA 930 $(\kappa = 6)$, and state-of-the-art TD-SARSA with LFA $(\kappa = 6)$ [6] 931 and Nevman-Pearson Detection (no sensing restrictions) [13]. 932 Although the algorithms in [6] and [13] do not inherently pos- 933 sess means to regulate the trade-off between CR throughput 934 and LU network interference, for the sake of this evalua- 935 tion, we have modified these algorithms to enable such a 936 mechanism: since [13] involves energy detection, false alarm 937 constraints can be brought in by modifying the detection 938 threshold; and we add this regulation to the observation and 939 access decision reliability control logic in [6]. In line with 940 the results of Fig. 5, we observe that LESSA consistently 941 achieves lower P_{MD} (hence lower interference to LUs) across 942 all ranges of P_{FA} . For instance, at a false alarm probability tar- 943 get of $P_{FA}=0.7$, LESSA achieves $P_{MD}=0.125$, as opposed 944 to 0.36 by the Neyman-Pearson Detector (despite no sensing 945 restrictions) [13] and 0.45 by TD-SARSA with LFA [6].

V. MA-LESSA: ALGORITHMS AND EVALUATION

In this section, we extend LESSA to both centralized 948 and distributed multi-agent deployments (MA-LESSA). With 949 respect to distributed deployments, we propose novel neighbor 950 discovery and channel access rank allocation schemes that are 951 embedded into LESSA – as depicted in Fig. 3 – along with 952 steps for sharing localized observations and access decisions 953 with neighbors, as well as the corresponding data aggregation. 954 The proposed neighbor discovery scheme involves an adapted 955 version of the Multi-band Directional Neighbor Discovery 956 (MDND) algorithm outlined in [22], with RSSI-thresholding 957 based modifications; furthermore, inspired by quorum-based 958 voting heuristics for cluster fallback mechanisms in Message 959 Oriented Middleware frameworks [23], we detail an access 960 order determination scheme for cooperative access among CRs 961 in the ensemble. As a part of our centralized deployment anal- 962 ysis, we retrofit MA-LESSA into the Purdue BAM! Wireless 963 CR network [25], with a gateway CR handling flow scheduling 964 to individual nodes in the network, making multi-hop routing 965 decisions, collaborating with other competitor networks, and 966 ensuring that Quality of Service (QoS) mandates are being 967 met throughout the scenario emulation period on the DARPA 968 SC2 Colosseum [18].

Use Italics to emphasise this block instead of bold text to maintain homogeneity throughout the article

Neighbor Discovery via RSSI-Thresholding: The MDND 971 scheme detailed in [22] employs the 2.4GHz Wi-Fi band 972 as a control channel for neighbor discovery in 60GHz data 973 environments. Adapting this scheme to multi-agent CR deploypr4 ments, we designate the band-edges as the control channel on which CRs communicate and coordinate their neighborhoods for channel access order allocation and data aggregation. At a pre-determined schedule, each CR broadcasts its control frames (with a frame header and node identifier) over the control channel, and upon receiving control messages from all its surrounding nodes, each CR checks if the expected RSSI of the radio signals corresponding to a certain node is above a threshold RSSI_{th}: if that is the case, it adds that node's identifier to its list of neighbors. The computational time complexity of the **RSSI** thresholding scheme for neighbor discovery is $O(J_C^2)$.

Channel Access Rank Allocation via Quorum-based 986 **Preferential Ballot:** With a similar control channel strategy 987 for channel access rank allocation, inspired by cluster fall-988 back schemes in queueing environments in enterprise software systems [23], we employ a quorum-based preferential ballot scheme to determine the order in which the estimated-idle subcarriers are accessed by the CRs in the network. This procedure starts only after a quorum has been achieved, i.e., the number of neighbors identified by an CR should be equal to or exceed a node-specific pre-defined number. Over the con-995 trol channel, each CR exchanges a ranked list of its neighbors the decreasing order of their respective RSSIs, with itself 997 being on the list at position-1 (ties are broken via uniform ran-998 dom choice). Upon receiving an RSSI-ranked list from one of 999 its neighbors, each CR assigns points to each ranked position, with higher ranks getting larger point values, and re-broadcasts an aggregated-ranked list of neighbors (with itself being on 1002 the list) with the ranking based on the point-values aggregated 1003 across all the ranked lists received from its neighbors (ties are broken via uniform random choice). If the aggregated-1005 ranked lists received from its neighbors matches the one at 1006 the CR for a pre-specified consecutive period of time, a consensus has been reached, so that the channel access order is determined by this harmonized-aggregated-ranked list. If the 1009 aggregated-ranked lists received from its neighbors differ from 1010 the one at the CR, then the CR repeats the re-ranking of these 1011 list members based on their new aggregated point-values and broadcasts the new aggregated-ranked list to its neighbors over the control channel. This repetitive process continues until 1014 a consensus is reached. The computational time-complexity 1015 of the quorum-based preferential ballot scheme for channel 1016 access rank allocation is $O(\tilde{T}J_C^2)$ [11], where \tilde{T} corresponds 1017 to the number of iterations involved until a consensus is 1018 reached – which depends on the mobility patterns of these 1019 nodes along with the temporal evolution of the peer-to-peer 1020 link qualities.

1021 A. Distributed MA-LESSA

Here, we evaluate the operational capabilities of MA-1023 LESSA in distributed settings. As illustrated in Fig. 1, 1024 operating under the same signal and observation models as 1025 in Section II, consider a network of 3 LUs operating in

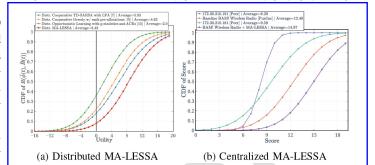

Fig. 7. CDF of the utility $R(\vec{\phi}(t), \vec{B}(t))$ (see (12)) for distributed MA-LESSA against state-of-the-art (a); CDF of the Score achieved during the DARPA SC2 Active Incumbent scenario emulation: comparison between BAM! Wireless CR network design retrofitted with MA-LESSA and other competitor network radio designs (including the baseline BAM! Wireless CR network) (b).

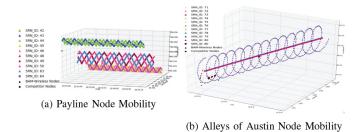

an 18-subcarrier radio environment, with their occupancy 1026 behaviors governed by Markovian time-frequency correla- 1027 tion structure (θ) , and 12 CRs intelligently trying to access 1028 white-spaces in the spectrum (cooperatively [6] or opportunis- 1029 tically [11]), with an added restriction of being able to sense 1030 only 1 subcarrier per CR per time-slot.

Fig. 7(a) plots the CDF of the utility achieved by MA- 1032 LESSA against other distributed multi-agent schemes in the 1033 state-of-the-art. We find that MA-LESSA outperforms the 1034 distributed, cooperative, ϵ -greedy TD-SARSA with Linear 1035 Function Approximation framework from [6] by 43%; it 1036 also outperforms the distributed, cooperative, time-decaying 1037 ε-greedy algorithm with channel access rank pre-allocations 1038 from [11] by 84%; and it outperforms the distributed, oppor- 1039 tunistic, g-statistics algorithm with ACKs (without chan- 1040 nel access rank pre-allocations) from [11] by 324%. These 1041 enhancements can be attributed to the fact that MA-LESSA 1042 exploits the LUs' occupancy correlation structure across both 1043 time and frequency (vs time only of [6] and the indepen- 1044 dence of [11]) and it leverages collaboration among CRs in 1045 the network for access order determination and sensed data 1046 aggregation.

B. Centralized MA-LESSA: DARPA SC2 Emulations

1048

In order to evaluate the performance of MA-LESSA in real- 1049 world settings, we retrofit it into the MAC layer (channel 1050 & bandwidth allocation) of our BAM! Wireless radio [25], 1051 by leveraging the aggregated PSD measurements obtained at 1052 the gateway node of our BAM! Wireless network, as shown 1053 in Fig. 2(b). We analyze its operational capabilities in the 1054 DARPA SC2 Active Incumbent scenario [17] emulated on 1055 the Colosseum [43]. The DARPA SC2 Active Incumbent sce- 1056 nario consists of a Terminal Doppler Weather Radar (TDWR) 1057 system functioning as the LU, and 5 competitor networks 1058 (ours included), each comprising 2 UNII WLANs: 2 Access 1059 Points (APs) and 4 STAtions (STAs) per AP, serving as the 1060 CRs, in a 10MHz radio environment (995MHz to 1005MHz), 1061 for 330 seconds of emulation on the Colosseum [17]. During 1062 the Active Incumbent scenario emulation, every competitor 1063 network receives network flows from the Colosseum, which 1064 need to be delivered to the appropriate destination nodes within 1065 the network, while satisfying the imposed QoS mandates per 1066

constituent nodes in the DARPA SC2 Payline

Fig. 8. The mobility patterns of constituent nodes in the DARPA SC2 Payline (a) and Alleys of Austin (b) scenarios. A Standard Radio Node (SRN) is a CR in DARPA SC2.

1067 flow (for example: max latency, min throughput, file transfer

1068 deadline, etc.). If the QoS mandates imposed on a particular 1069 network flow have been satisfied for a pre-specified period of 1070 time, then the Individual Mandates (IMs) associated with the

1071 flow are said to have been met. Let \mathcal{V}_t be the set of IMs achieved by a participant network 1073 in time-slot t, and let p_v be the points received for satisfy-1074 ing an IM $v \in \mathcal{V}_t$: we define the score of a participant network 1075 corresponding to a certain time-slot t as $\sum_{v \in \mathcal{V}_t} \mathbf{p}_v$ [17]. We 1076 evaluate the performance of MA-LESSA retrofitted into our standard BAM! Wireless radio [25], and compare it against baseline channel and bandwidth allocation scheme that 1079 involves the weighted combination of PSD observations and 1080 collaboration data received from the other competing networks (titled "Baseline BAM! Wireless Radio [Purdue]"), and against 1082 the designs of other competitors (identified by their collaboration network registered IP address [26], "172.30.210.191 1084 [Peer]" and "172.30.210.181 [Peer]"). Fig. 7(b) plots the CDF of the score achieved: remarkably "BAM! Wireless Radio + 1086 MA-LESSA" outperforms the baseline BAM! Wireless design by 21% in average score, and outperforms the competitors by 1088 56% and 81%, respectively. This result shows the potential of MA-LESSA to optimize higher-layer metrics (the network 1090 score) thanks to improved detection of white-spaces. To evaluate the proposed neighbor discovery (RSSI thresholding) 1092 and channel access rank allocation (quorum-based preferen-1093 tial ballot) heuristics from a computational time complexity 1094 perspective, we retrofit these schemes into the control chan-1095 nel design, collaboration, and data aggregation modules of the 1096 Purdue BAM! Wireless radio [25], and analyse their feasi-

1097 bility in emulations of highly mobile real-world scenarios –

1098 namely, military deployments in the Alleys of Austin sce-

nario [32] (urban: $5 \times [9 - \text{guardsmen} + 1 - \text{UAV}]$) and

1100 disaster relief deployments in the Payline scenario [31] (urban:

 $_{1101}$ 5 × [9 – EMTs + 1 – HQ]). Along with the scenario-specific

1102 node mobility patterns (Fig. 8), the results of these emula-

1103 tions are shown in Fig. 9: neighbor discovery list changes are

1104 minimal in spite of node mobility (with an RSSI threshold

1105 of 22dB), and distributed convergence of channel access rank

1106 allocation across the ensemble is achieved within the first few

1108 C. LESSA on an ESP32 WLAN Testbed

1107 iterations in any given 10s time-step.

We employ 8 ESP32 radios [19], each embedded on a GCTronic e-puck2 robot [24], categorized into a network of

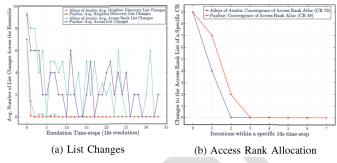

Fig. 9. Evaluation of neighbor discovery and channel access rank allocation: average number of neighbor discovery and channel access rank list changes across the ensemble (a); and convergence visualization of channel access rank allocation in a specific 10s time-step for specific CRs in the network (b).

3 LUs (and their 3 corresponding sinks) occupying 6 subcar- 1111 riers in the 2.4GHz Wi-Fi spectrum; and 2 independent CRs, 1112 each having the capability to sense only one channel at a time. 1113 With 2 CRs, the overall sensing restriction of the CR network 1114 is thus $\kappa=2$ (work split over 2 ESP32 radios due to design 1115 limitations). The 3 LUs occupy the spectrum according to 1116 a Markovian time-frequency correlation structure (described 1117 by (7)), with parameters $p_{0,0}=0.1,\ p_{0,1}=p_{1,0}=0.3,\ 1118$ $p_{1,1}=0.7$ and $q_0=0.3,\ q_1=0.8$. We simulate the occu- 1119 pancy behavior of the LUs according to this time-frequency 1120 correlation structure, and solve for the spectrum sensing and 1121 access policy using LESSA, by mimicking the observational 1122 capabilities of the actual ESP32 radios. Note that this step is 1123 performed on a PC.

The simulated LU occupancy behavior and the time-slot 1125 specific channel access decisions (derived through LESSA), 1126 are stored in databases for export onto the ESP32 network. 1127 In time-slot t, a peer-to-peer communication link l_{ij} is estab- 1128 lished between an ESP32 LU $j \in \{1, 2, 3\}$ and its designated 1129 sink $i \in \{1, 2, 3\}$, over a subcarrier $k_{l_{ij}} = k \in \{1, 2, ..., 6\}$, as 1130 determined by the exported LU occupancy database. These 1131 channel allocations are done orthogonally at the LUs, so 1132 that $k_{l_{ij}} \neq k_{l_{i',j'}}, \forall i, i' \in \{1,2,3\}, j,j' \in \{1,2,3\}.$ In the next 1133 synchronized time-slot t+1, this link l_{ij} moves to channel 1134 $k' \in \{1, 2, ..., 6\}$, again as determined by the LU's behavioral 1135 rules maintained in the exported occupancy database. This 1136 same procedure takes place for the other two LU communi- 1137 cation links in every time-slot until the end of the evaluation 1138 period. Although the PC-based POMDP solver employs a sin- 1139 gle CR which can access 2 subcarriers at a time in order to 1140 deliver its flows (see the access part of the POMDP formu- 1141 lation in Section II-D), we employ 2 ESP32 CR radios in 1142 the network (serving as one), with the channel access work 1143 synchronously and evenly split between the two, due to the 1144 actual physical design limitations of the ESP32 radio, each 1145 able to access only one channel at a time. More specifi- 1146 cally, we split the 2-channel access decision in time-slot t, as 1147 determined by the time-slot specific POMDP channel access 1148 database, into a 1-channel access action at each ESP32 CR 1149 radio. Next, based on whether the channel access at the 2 1150 ESP32 CR radios was successful, we compute the success rate 1151 as $\frac{1}{2}\sum_{j=1}^{2}\mathcal{I}[B_{k_{CR_{i}}}(t)=0]$, where $B_{k_{CR_{i}}}(t)\in\{0,1\}$ is the 1152

 $_{1153}$ occupancy variable of the channel accessed by CR j in time- $_{1154}$ slot t. The implementation of LESSA on this ad-hoc WLAN $_{1155}$ testbed demonstrates a channel access success probability of $_{1156}$ 96% across an evaluation period of 300s.

VI. CONCLUSION

In this paper, we formulate a learning-based spectrum sens-1159 ing and access problem in resource-constrained radio ecosys-1160 tems as an approximate POMDP, which leverages learning 1161 of the LU occupancy correlation model via the Baum-Welch 1162 algorithm and solving for an approximately optimal sensing 1163 and access policy via the PERSEUS algorithm. We pro-1164 pose fragmentation, Hamming distance state filter heuristics, and Monte-Carlo methods to alleviate the inherent computa-1166 tional complexity of PERSEUS. Through system simulations, we demonstrate the advantages of exploiting the correlation 1168 structure – as opposed to Neyman-Pearson Detection which 1169 assumes independence; adapting the spectrum sensing decision to enhance white-space detection – as opposed to Viterbi, which uses a fixed sensing strategy; and a parametric learning and adaptation framework – over model-free Deep Q-Network 1173 designs. We also demonstrate the feasibility of a concurrent 1174 learning and decision-making framework, as opposed to state-1175 of-the-art correlation-coefficient based clustering algorithms, 1176 which rely on pre-loaded datasets for determining the correla-1177 tion in the LU occupancy behavior. Our framework enables a 1178 critical feature in practical scenarios: the ability of the CR to 1179 regulate the interference caused to LUs, by adjusting a penalty 1180 parameter. Also, extending our single-agent model to multi-1181 agent settings, we demonstrate superior performance over the 1182 state-of-the-art, in both centralized and distributed deployment 1183 settings (collaborative and opportunistic access).

Bharath Keshavamurthy (Graduate Student Member, IEEE) received the B.E. degree in electronics and communication engineering from Visvesyaraya Technological University, India, in 2016, the M.S. degree in electrical and computer engineering from Purdue University, West Lafayette, IN, USA, in 2020. After 15 months in the Ph.D. program in Electrical and Computer Engineering at Purdue University, he is currently pursuing a Ph.D. in Electrical Engineering at Arizona State University, Tempe, AZ, USA. Previous industrial

1337 Research and Development roles include a Graduate Intern at DC-NXOS, 1338 Cisco Systems Inc; a Senior Software Engineer, OSS R&D, Nokia Digital 1339 Platforms; and a Networking Intern, Radio Access Networks, Ericsson R&D. 1340 As a Graduate Research Assistant with Purdue University, he worked on 1341 the BAM! Wireless Cognitive Radio Design team for DARPA SC2 from 1342 2018 to 2019. His current research interests include multifaceted UAV fleet 1343 automation, 3-D coverage for 6G cellular networks, millimeter-wave V2X 1344 propagation modeling and experimentation, and massive MIMO system 1345 design.

Nicolò Michelusi (Senior Member, IEEE) received 1346 the B.Sc. and M.Sc. degrees (Hons.) from the 1347 University of Padova, Italy, in 2006 and 2009, 1348 respectively, the M.Sc. degree in telecommunica- 1349 tions engineering from the Technical University of 1350 Denmark, Denmark, in 2009, as part of the T.I.M.E. 1351 double degree program, and the Ph.D. degree from 1352 the University of Padova in 2013. From 2013 1353 to 2015, he was a Postdoctoral Research Fellow 1354 with the Ming-Hsieh Department of Electrical 1355 and Computer Engineering, University of Southern 1356

California, Los Angeles, CA, USA, and from 2016 to 2020, he was an 1357 Assistant Professor with the School of Electrical and Computer Engineering, 1358 Purdue University, West Lafayette, IN, USA. He is currently an Assistant 1359 Professor with the School of Electrical, Computer and Energy Engineering, 1360 Arizona State University, Tempe, AZ, USA. His research interests include 1361 5G/6G wireless networks, millimeter-wave communications, stochastic and 1362 distributed optimization, and federated learning over wireless. He received 1363 the NSF CAREER Award in 2021. He was the Co-Chair of the Distributed 1364 Machine Learning and Fog Network Workshop at IEEE INFOCOM 2021, 1365 Int. Wireless Communications Symposium at IEEE GLOBECOM 2020, the 1366 IoT, M2M, Sensor Networks, and Ad-Hoc Networking Track at IEEE VTC 1367 2020, and the Cognitive Computing and Networking Symposium at ICNC 1368 2018. He is an Associate Editor of the IEEE TRANSACTIONS ON WIRELESS 1369 COMMUNICATIONS and a reviewer for several IEEE journals.
